

Ecological Studies on the Fauna Associated with Economic Seaweeds of South India-2.

Distribution in space and time

India*

Introduction

Quantitative studies are of great value in ecological investigations as the numerical, volumetric or gravimetric estimations of the populations provide estimates of productivity and standing crop and enable numbers and weights of animals in a given habitat to be compared both in time and in space. Colman (1940) was the first to estimate the numerical abundance of the fauna inhabiting intertidal seaweeds. Later, many attempts have been made by various workers (Wieser, 1952, 1959; Chapman, 1955; Glynn, 1965; Hagerman, 1966; Jansson, 1967; Moore, 1971) to study the algal communities in the temperate waters. From the Indian coasts, the only study of similar nature is by Sarma and Ganapati (1972) who studied the numerical distribution of phytal fauna on 13 species of seaweeds from the intertidal regions of Visakhapatnam coast. The spatial and temporal distribution of the macrofauna inhabiting intertidal seaweeds at Mandapam Camp is discussed in this paper.

Materials And Methods

The intertidal region at Mandapam Camp (Lat. 90° 16' N; Long 79° 12'E) presents a typical surf beaten tropical rocky shore. The intertidal substratum, formed of sandstone, has a vertical expanse of seven metres. 25 belt transects, each of 25 cm in breadth, running from the highest higher highwater level (HHHWL) to the infralittoral fringe were fixed. In each month, one transect was selected at random for sampling. Monthly samplings were made from January to December 1970 during the neap tides. From each transect, samples were collected by scraping the algae present in a 25 cm² quadrat at intervals of 50 cm from the HHHWL to the infralittoral fringe. The highest vertical limit of the algae was at the quadrat situated at a distance of 4 m from the HHHWL. The levels of the quadrats in relation to the zero of Chart Datum were: 4.0 m = +0.60; 4.5 m = +0.50; 5.0 m = +0.40; 5.5 m = +0.35; 6.0 m = +0.30; 6.5 m = +0.25. In the laboratory each sample was washed thoroughly and holdfasts of algae teased out. The washings were filtered through a mesh (1.0 mm) which retained the macrofauna. The animals were sorted out into various groups under a dissection microscope. The sediment content was estimated as percentage volume of the total from each quadrat.

1. Polychaetes

Table 1 presents the vertical distribution of polychaetes during the period January—December 1970. During January, when the observations commenced, the distribution of polychaetes was more or less uniform on the intertidal algal bed. The period February to April recorded a gradual downward migration in the population from the + 0.60 level to 0+.40 and lower levels. The least density was during April, when the distribution was limited to a narrow belt in between + 0.25 and + 0.40 levels. An upward migration in the distribution during May. During July-December, population density increased considerably at all levels studied, resulting in a luxuriant population of intertidal polychaetes. The highest density at + 0.35 level during August shifted to + 0.40 level during September—December.

December	640	768	1584	—	—	—

— = Collections were not possible from these levels due to severe wave action.

2. Gastropods

The vertical distribution of gastropods during the period under observation (Table 2) showed two trends: a wider distribution on the intertidal algae at levels lower than + 0.40 during January—July and a narrower but more abundant distribution at the higher levels (+ 0.30 to + 0.60) during August–December. Maximum densities were found at + 0.40 and + 0.50 levels. They were either totally absent or present in small numbers at the lower levels (+ 0.30 and + 0.25) during August–September.

Table 3. The quantitative distribution of bivalves (No/m²) on the inter-tidal algae during the period January–December 1970.

December	2576	2864	368	—	—	—

— Collections were not possible from these levels due to severe wave action.

3. Bivalves

Although the bivalves were more or less uniformly distributed on the intertidal algae during January, a characteristic feature during the period February–May was the confinement of the upper and lower limits to the levels + 0.50 and + 0.30 respectively (Table 3). During the rest of the year an upward migration by shifting the upper limit to +0.60 level was evident. Maximum densities during this period were around + 0.40 level, with the higher and lower levels indicating marked reduction in numbers.

Table 4. The quantitative distribution of amphipods (No/m³) on the inter-tidal algae during the period January–December 1970.

— — Collections were not possible from these levels due to severe wave action.

4. Amphipods

A tendency to concentrate at levels between + 0.35 and + 0.40 was exhibited by amphipods during February–May period (Table 4). During June and July a clear-cut upward migration to the level + 0.60 was noticed. August–December recorded the highest densities of amphipods during the year. Maximum concentrations during this period were at levels + 0.40 and + 0.50.

Table 5. The quantitative distribution of isopods (No/m²) on the inter-tidal algae during the period January - December 1970.

5. Isopods

Table 5 presents the numerical distribution of isopods. It appears from the data that they preferred to occupy rather lower levels (+ 0.30 to + 0.40) during February–April. During May and June their distribution was irregular. However, during July–December, a clear-cut preference to higher levels (> + 0.35) was evident. Maximum densities were recorded at + 0.40 during this period.

Table 6. The quantitative distribution of harpacticoids (No/m³) on the inter-tidal algae during the period January–December 1970.

December	6240	13840	19904	—	—	—

— = Collections were not possible from these levels due to severe wave action.

6. Harpacticoids

High densities of harpacticoids were recorded throughout the year at various levels on the intertidal algae (Table 6). The highest densities during February–May were at + 0.40 level. May, June and July witnessed an upward shifting of the concentrations to + 0.50 level. Very dense populations were recorded at all levels higher than around + 0.30 during August–December.

— Collections were not possible from these levels due to severe wave action.

7. Miscellaneous groups

This included porifera, turbellaria, ostracoda, tanaidacea, decapoda and egg masses. They were present in any appreciable quantity only during August–January. A striking decline in the abundance was evident during February–April (Table 7). Further, their reduction in numbers or absence from intertidal algae was conspicuous during March–July. Dense populations appeared at the lower levels (+ 0.25 and + 0.30) during August which migrated to higher levels (+ 0.40 and + 0.50) during September–December. The upper limit of their distribution was + 0.60 level during this period.

Discussion

The spatial and temporal distribution of the fauna can be related to the changes in the hydrographic characteristics of the surface water, meteorological changes in the climate and seasonal succession in algal communities. The surface water temperatures during 1970 were as follows: $<28^{\circ}\text{C}$ during October-December; $28-30^{\circ}\text{C}$ during January, February and June-September; $>30^{\circ}\text{C}$ during March-May. The surface water salinity was $<32\%$ during January and October-December and $>32\%$ during February-September. The highest salinity (36.39%) was during July. A clear-cut change in the wind velocities is apparent. During January-May, the shore experiences normal wind velocities up to 10 knots per hour while wind velocities as high as 16 knots per hour are common during June-December (Indian Daily Weather Reports, 1970). The period October-December is also characterised by stormy weather and very turbulent sea. While the high wind velocities are thus typical of the south-west monsoon (June-September) and the North-East monsoon (October-December) periods, the bulk of the rainfall is limited to the November-January period (La Fond, 1958). The distribution of the dominant species of algae and the sediment content are given in Table 8.

A critical analysis of the distribution of the algae and the inhabiting fauna reveals a very interesting pattern. During the summer months (February - May) the algae occupy a lower level on the intertidal region. This period is characterised by intensive insolation and high temperatures. The tidal effect is very pronounced on the intertidal region, resulting in a narrow, more or less mixed belt of intertidal algae. It has been found that during this period of intensive desiccation, comparatively rich populations of polychaetes, amphipods and harpacticoids are supported by the intertidal algae. The other groups of animals are less dense and distributed in between +0.40 and +0.50 levels. The sediment content of the algae varied over a wide range during this period. The distribution pattern changed by the onset of the South-West monsoon. The severe wind and the resultant wave action shifted the upper limit of the algae to a much higher (+0.60) level. The effects of low tides were nullified by the high waves wetting the intertidal region. This resulted in a wider and more marked distribution of the algal communities. This situation was intensified by the North-East monsoon during October-December. Not only did this result in an upward shifting of the upper limit of the algal belt, but also the appearance of many algal species which are otherwise subtidal, at the +0.25 level. The sediment contents were high at the higher levels. The cryptofauna also exhibited a similar upward migration along with the algae. Denser populations of all groups were recorded during this period, most of which however, preferred a higher level on the shore.

The vertical distribution of the animals inhabiting seaweeds is more strongly influenced by the nature of the substratum than is the distribution of normal intertidal fauna of rocky shores (Wieser, 1952). Therefore, the upper limits of the algae will determine the upper limits of many organisms living on algae. It is evident from the tables that two types of organisms inhabit the intertidal algae: one group lives on it permanently throughout the year and the other only during those months when the algae are constantly wetted by waves and tides. It is also evident that such types are constituted not by taxonomic groups, but by individual species or even ecological variants.
